COOLING CHARACTERISTICS OF A TRANSPIRATION-COOLED AFTERBURNER WITH A

POROUS WALL OF BRAZED AND ROLLED WIRE CLOTH

By William K. Koffel

SUMMARY

Cooling data were obtained for a transpiration-cooled afterburner having a porous combustion-chamber wall of brazed and rolled wire cloth for a range of exhaust-gas temperatures from 1200° to 3340° R, total flow ratio of cooling air to combustion gas of 0.025 to 0.106, and pressure altitudes of 15,000 to 45,000 feet. The data are successfully correlated over a range of Reynolds number from 75,000 to 1,500,000, based on the distance downstream of the leading edge of the porous wall.

Maximum wall temperatures based on the cooling correlation were determined for a porous wall of uniform permeability at sea-level takeoff and for flight Mach numbers of 0.8, 1.5, and 2.0 at an altitude of 35,000 feet. The cooling-air requirements were nearly independent of the flight conditions. A total flow ratio of cooling air to combustion gas of about 0.032 can maintain a maximum wall temperature of 12100 R with an exhaust-gas temperature of 3700° R. The total flow ratios with a uniform permeability distribution and air flows sufficient to limit the maximum wall temperatures to 1210°R are about 15 percent higher than the minimum total flow ratios corresponding to a variable-permeability wall with a constant wall temperature of 1210° R. The total flow ratios for a maximum wall temperature of 1210° R with a wire-cloth afterburner are about 16 percent of the total flow ratios required to cool a stainless-steel afterburner wall convectively to a maximum wall temperature of 1760° R with exhaust-gas temperatures of 3200° and 3700° R. The analysis of cooling-air requirements for the previously mentioned flight conditions indicated that cooling-air static pressures must be closely controlled, especially at a flight Mach number of 2.0.

INTRODUCTION

The satisfactory cooling of high-thrust-augmentation afterburners for supersonic aircraft requires large amounts of cooling air. These large quantities of cooling air, whether supplied from the ambient-air

3295

탱

322

stream or from compressor bleed, involve large losses in net thrust. These losses, however, can be minimized through the use of more effective cooling methods. Transpiration cooling has been shown theoretically (ref. 1) to be more effective than film cooling or the conventional method of afterburner cooling by forced convection. The high effectiveness of transpiration cooling was experimentally verified in a preliminary investigation of a transpiration-cooled afterburner having a wall of sintered porous stainless steel (ref. 2). The commercial sintered porous stainless steel used in the preliminary investigation of transpiration cooling for afterburners was unsuitable for use in flight afterburners because of low strength-to-weight ratio, poor control over the uniformity of permeability, and fabrication difficulties.

In the search for more suitable porous materials, wire cloth was investigated (ref. 3) because of its high strength-to-weight ratio, availability in large sheets, ease of fabrication, and low cost compared with sintered porous metals. The NACA Lewis laboratory designed and built a transpiration-cooled afterburner with a porous wall of the brazed and rolled wire cloth, described in reference 3. This burner was operated on a turbojet engine to determine the feasibility of a wire-cloth transpiration-cooled afterburner and to evaluate its cooling performance.

The cooling data from the wire-cloth afterburner are reported herein for pressure altitudes of 15,000 to 45,000 feet, exhaust-gas temperatures from 1200° to 3340° R, and total flow ratios of cooling air to combustion gas of 0.025 to 0.106. A cooling correlation is derived from these data. This correlation is then used to predict the cooling-air requirements of this afterburner with exhaust-gas temperatures of 3200° and 3700° R for several typical flight conditions of a supersonic airplane. A comparison is also made between the cooling-air requirements of this afterburner with transpiration cooling and with conventional forced-convection cooling. The experimental cooling correlation is briefly compared with the approximate theory of Rannie and Friedman (refs. 4 and 5) for transpiration cooling with turbulent boundary-layer flow.

APPARATUS AND INSTRUMENTATION

Test Installation

The wire-cloth afterburner was mounted on a conventional axial-flow turbojet engine installed in an altitude test chamber. The test installation aft of the turbine flange is shown in figure 1. The engine and afterburner assembly were mounted on a bed plate suspended in the altitude chamber in such a manner as to permit the measurement of jet thrust. A sectional view of the afterburner is shown in figure 2 together with details of the flame holder and fuel-spray bars. The configuration between

the turbine flange and the beginning of the porous wall, including the fuel-spray bars and flame holder, was identical with the high-performance afterburner configuration of reference 6, which was evolved from configuration C of reference 7.

Cooling air from an independent source was filtered through 100 square feet of 1-inch-thick Fiberglas filter media that retained particles greater than 1 micron. The flow was measured by means of an A.S.M.E. standard thin-plate orifice. The plenum chamber and the high-temperature impermeable wall upstream of the porous-wall section were Inconel, and the cooling-air side of the mild steel shroud was painted with zinc chromate primer in order to eliminate the possibility of clogging the wire cloth with fine scale.

The engine fuel was clear unleaded gasoline of 62-octane rating, and the afterburner fuel was MIL-F-5624A, grade JP-4.

Wire-Cloth Porous Wall

The porous combustion-chamber wall was made from wire cloth that was brazed and rolled, for permeability reasons, as described in reference 3. The particular cloth used was monel 21x70 twilled Dutch weave (designated cloth B in ref. 3) sprayed with three coats of silver solder per side and brazed and rolled to a 35-percent reduction in original thickness. The average final thickness was Q.0274 inch, and the average permeability coefficient K was about 1×10-8 square inch. The tapered combustion chamber was lined with a porous wall made from 20 pieces of wire cloth formed into shallow channels. Each channel was 1/2 inch deep by about 41 inches long and tapered in width from about 4 inches at the upstream end to about 3.5 inches at the downstream end. The channels were spot-welded to angles (fig. 3) that were fastened to the structural shroud by blind rivets. The permeability of each channel differed slightly from the average permeability for all the channels. It was expected that the cooling-air static pressure would vary somewhat circumferentially because of the tangential inlet to the plenum chamber. Therefore, the channels were arranged in an order that would tend to produce a circumferentially uniform distribution of cooling air.

The newly fabricated porous combustion-chamber wall is shown in figure 4(a). The channels of wire cloth were permanently bulged toward the center line of the combustion chamber after the initial operation of the engine. Figure 4(b) shows the bulged channels at the end of the cooling investigation with cooling passage heights of about 3/4 to 7/8 inch in midchannel. The method of suspending the wire cloth caused a minimum of disturbance to the cooling-air film on the gas side of the porous wall, and the bulging of the channels reduced tensile stresses in the wire cloth caused by pressure forces. The impermeable wall

3295

upstream of the porous wall was forced-convection cooled by the cooling air before it flowed into the 20 dead-ended cooling-air passages.

Instrumentation

The research instrumentation for measurement of temperatures and pressures at several stations through the turbojet engine was the same as in reference 6. The location of each temperature and pressure measurement on the afterburner is shown in figure 5. The five principal stations of instrumentation on the porous wall were 24, 32.6, 41, 49.6, and 57.5 inches downstream of the quick-disconnect flange at the combustion-chamber inlet (see fig. 2).

Details of a typical group of instrumentation are shown in figure 6. The cooling-air temperature probes had butt-welded iron-constantan thermocouple junctions shaved smooth to 0.010-inch diameter. thermocouples on the wire cloth were 28-gage (0.013-in.) chromel-alumel wire individually wrapped with silicone-treated asbestos insulation and overbraided with Fiberglas insulation. The orientation and application of the spot-welded junctions on both sides of the wire cloth can be seen in figure 6. There were only four thermocouples on the gas side of the wire cloth because of difficulties in installation. The shroud temperatures were measured with 22-gage (0.025-in.) iron-constantan thermocouples (not shown in fig. 6) spot-welded to the outside of the shroud. The longitudinal profile of static pressure in the combustion chamber was determined by means of 0.080-inch outside diameter by 0.010-inch wall stainless-steel tubes sweat-brazed into the wire cloth and ground flush. The flexibility of these tubes and the method of leading them out of the passage permitted the wire cloth to assume a natural curve with minimum distortion of the cloth at the point of pressure measurement.

Strain-gage pressure pickups were mounted on the cooling-air plenum chamber and on the combustion-chamber wall at the flame-holder station to obtain the static-pressure pulsations in the cooling air and combustion chamber during ignition and normal afterburning. The pressure pulsations were recorded on a two-channel oscillograph.

TEST PROCEDURE

Air-flow calibrations were obtained for each piece of wire cloth before fabrication into the porous wall. These calibrations were taken at points where temperature instrumentation was later applied. Additional cold-air-flow calibrations were made of the assembled porous wall, as a whole, at several ambient pressure levels before and during the cooling investigation to detect any over-all change in the air-flow calibrations from plugging by fuel or combustion residues or from oxidation of the

brazing alloy. Nonafterburning check points were also made during the cooling investigation as a check on instrumentation and changes in the wire cloth.

The data are presented in tables I to V, and the approximate range of some of the variables are given in the following table for an inlet cooling-air temperature of 535° R:

Pressure altitude, ft	Compressor air flow, lb/sec	Cooling-air flow, W _a , lb/sec	Exhaust- gas total temperature, Tg,2, CR	Type of test
Sea level 15,000 35,000 45,000	0 0 0	0.970-5.810 1.255-4.344 .903-2.849 1.49-1.79	⁸ 535 ⁸ 535 ⁸ 535 ⁸ 535	Check on air- flow calibration and plugging of wire cloth
15,000 35,000	45.8 25.5	1.2-3.8 .83-2.7	1200 1250	Cooling, non- afterburning
15,000 35,000 45,000	45.8 25.5 15.6	1.37-3.25 1.26-3.16 1.49-1.79	2580-3010 1800-3340 3185	Cooling, afterburning

^aApproximate ambient-air temperature.

The cooling-air flow was varied at a given pressure altitude and fuel-air ratio between the following limits:

- (1) Minimum static-pressure difference Δp across upstream edge of wire cloth of 0.5 lb/sq in. to prevent reverse flow of combustion gas through wire cloth
- (2) Maximum Δp across downstream edge of wire cloth of 6 lb/sq in. to avoid bursting channels of wire cloth
- (3) Maximum wire-cloth temperature of 1460°R to avoid excessive rate of plugging from oxidation of silver solder
- (4) Maximum turbine-outlet gas temperature of 1625° R to protect turbine from over-temperature

METHODS OF CALCULATION AND ANALYSIS

Cooling-Air Flow

Iocal values of the cooling-air flow normal to a unit of wire-cloth surface area (pV)_a were computed for two channels, channel 1 having the hottest and channel 9 having the coldest porous-wall temperatures. This computation was based on the air-flow calibrations of figure 7, the thickness of each channel, the respective longitudinal profiles of cooling-air static pressure, and the assumption that the longitudinal profile of combustion-gas static pressure was circumferentially uniform.

(Symbols are defined in appendix A.) The ordinate $\frac{\Delta(p^2)}{\tau} \left(\frac{\mu_0}{\mu}\right)^{\frac{T_0}{T}}$ of figure 7 is in effect a measure of the pressure drop per unit thickness across the porous wall, and the abscissa $(\rho V)_a \frac{\mu_0}{\mu}$ is the reduced weight flow of cooling air per unit of wire-cloth surface area. The viscosity and temperature ratios, μ_0/μ and $(\mu_0/\mu)^2 T_0/T$, reduce the air-flow data to NACA standard temperature. A theoretical analysis in reference 8 indicates that the profile of air temperature across a porous wall should practically coincide with profile of metal temperature except for a very short distance on the side the air enters the wall. Consequently, the viscosity- and temperature-ratio factors should be evaluated at the average local wall temperature. Measured wall temperatures on either side of the wire cloth in this afterburner were within 20° R of each other, so for convenience the factors were evaluated at the temperature measured by the air-side thermocouples, which were installed at each station of channels 1 and 9.

The calculated total cooling-air flows in a later section, Cooling-Air Requirements Calculated from Cooling Correlation, were obtained from the step-by-step summation of $\pi D(\rho V)_{g} \Delta x$.

Exhaust-Gas Temperature

The total temperature of the exhaust gas was calculated from the exhaust-nozzle total pressure P_{68} , measured jet thrust, velocity coefficient, and gas flow by the following equation (ref. 7):

$$T_{g,2} = \left(\frac{F_{j,m}}{C_v}\right)^2 \left(\frac{g}{2R}\right) \left(\frac{\gamma_g-1}{\gamma_g}\right) \left\{\frac{1}{W_{g,68}^2 \left[1 - \left(\frac{p_0}{P_{68}}\right)^{\frac{\gamma_g-1}{\gamma_g}}\right]}\right\}$$
(1)

3295

The values of R were computed according to the method of reference 9, and the jet velocity coefficient was determined to be 0.97 from data presented in reference 10.

Local Combustion-Gas Temperatures

Local values of the combustion-gas total temperature $T_{g,x}$ with afterburning were computed from the empirical equation (ref. 11)

$$\frac{T_{g,x} - T_{g,1}}{T_{g,2} - T_{g,1}} = \sin \frac{\pi}{2} \frac{x^{i}}{L}$$
 (2)

where $T_{g,1}$ is assumed equal to the turbine-discharge gas temperature, and $T_{g,2}$ is the exhaust-gas total temperature. Equation (2) makes no allowance for possible hot streaks and implies a uniform transverse profile of combustion-gas temperature. Hot streaks undoubtedly were present, although observation of the combustion color and pattern by means of a periscope directed up the burner axis showed good circumferential uniformity. The transverse temperature profile was made as uniform as possible in a previous investigation of the radial fuel-air distribution when this same configuration had a convection-cooled impermeable wall.

For nonafterburning cooling data, local values of bulk total temperature $\textbf{T}_{g,X}$ were assumed equal to the turbine-discharge gas temperature $\textbf{T}_{g,1}.$

Correlation of Cooling Data

Cooling data from five stations along the two typical channels of wire cloth were correlated by plotting the temperature-difference ratio $(T_w - T_a)/(T_g - T_a)$ against the coolant-flow ratio $(\rho V)_a/(\rho U)_g$ for constant values of bulk Reynolds number. The flow over the porous wall was believed to be similar to the boundary-layer flow over a flat plate, so that the length used in the Reynolds number was taken as the distance from the leading edge of the porous wall. Consequently, the temperature-difference ratios and the coolant-flow ratios are local values corresponding to the local Reynolds numbers. The viscosity of the combustion gas was assumed to be the same as for air given in table 2 of reference 12 and was evaluated at the film temperature T_f . The quantity $(\rho U)_g$ was assumed identical to the local one-dimensional value of total weight flow per unit of combustion-chamber flow area.

The wall temperature T_w in the temperature-difference ratio $(T_w - T_a)/(T_g - T_a)$ was measured on the cooling-air side of the wire cloth but can be considered practically to represent the wall temperature on the hot-gas side because of the small difference in measured temperatures across the wire cloth in this afterburner.

Cooling-Air Requirements Calculated from Cooling Correlation

The experimental cooling correlation of this investigation was used to calculate the longitudinal profile of porous-wall temperature in this afterburner. The conditions analyzed are given in the following table:

Flight condition	Flight Mach number	Altitude, ft	Exhaust-gas total temperature, Tg,2,
A B B C	0 .8 .8 1.5 2.0	Sea level 35,000 35,000 35,000 35,000	3700 3700 3200 3700 3700

The turbine-discharge temperature was 1710° R for all conditions. The cooling-air static pressure and the permeability of the porous wall were assumed to be absolutely uniform, and the air-flow calibration of the porous wall was assumed to be identical with the mean calibration curve of figure 7. With a uniform permeability, most of the porous wall will be overcooled except for some peak temperature region, which must not exceed the maximum allowable operating temperature of the porous material. The calculated maximum wall temperatures were plotted against total flow ratio for each flight condition. It should be kept in mind that wall temperatures calculated from the cooling correlation are assumed to be uniform around the circumference at each station. Usually, a safety factor must be allowed for random hot spots in the porous wall caused by hot streaks in the combustion gas or by local areas that have less than the mean permeability.

Minimum cooling-air flow. - The minimum cooling-air flow for a given temperature limit results when the wall temperature is maintained constant at the maximum allowable operating temperature of the porous material by use of an infinitely variable permeability distribution along the porous wall. The assumption of a constant wall temperature makes it possible to compute the minimum cooling-air distribution and the minimum total flow ratio directly from the cooling correlation without considering the distributions of permeability that would be

required to provide the minimum cooling-air distribution. Although it is not practical to vary the permeability distribution for each flight and operating condition in an actual afterburner, the minimum flow ratios are useful for reference and for examination of trends. Minimum total flow ratios were therefore also computed for flight conditions A to D with a constant porous-wall temperature of 1210° R.

Longitudinal profile of combustion-gas static pressure. - The static-pressure profile along the length of the combustion chamber was calculated step-by-step from well-known one-dimensional flow relations for momentum pressure drop in a constant-area duct and the isentropic variation of Mach number with area ratio. The friction pressure drop, which was assumed to be small relative to the momentum pressure loss, was neglected.

Cooling-air pressure and temperature. - The cooling air was assumed to have been bled from an interstage of the compressor (at a compressor efficiency of 0.85) at a pressure high enough to allow for a pressure drop of 1 pound per square inch through valves and ducting to the upstream edge of the porous wall. The pressure drop across the porous wall was limited to a minimum of 1 pound per square inch for practical control, and to a maximum of 6 pounds per square inch to prevent bursting the channels of wire cloth. The cooling-air pressure and temperature were presumed to be uniform in all cooling-air passages. Convective heat transfer to the cooling air by the impermeable wall upstream of the porous wall was assumed to raise the air temperature 50° above that corresponding to the compressor bleed temperature.

Cooling-Air Requirements with Forced-Convection Cooling

Cooling-air requirements for forced-convection cooling of this afterburner with ram air were calculated for exhaust-gas temperatures of 3200° and 3700° R for flight condition B from data in reference 13 and the cooling correlation of reference 11.

RESULTS AND DISCUSSION

Typical Data

Figure 8 shows typical measured circumferential profiles of the cooling-air static pressure and wire-cloth temperature. The static-pressure profiles shown result from the tangential inlet on the plenum chamber and the previously mentioned order of assembling the channels of wire cloth. As would be expected, the temperature profiles are the reverse of the pressure profiles. Figure 8 shows that channel 1 was generally the hottest and channel 9 the coldest, with or without afterburning.

出-2

Typical longitudinal profiles for the wire-cloth afterburner are shown in figure 9. The importance of eliminating circumferential gradients in cooling-air static pressure and in permeability is obvious from the 530° R variation in wall temperature at station 62 in figure 9(a). Part of the circumferential temperature spread in this afterburner would have been averted if there had been no circumferential pressure gradient in the cooling air. The pressure gradient could have been reduced by a better plenum-chamber inlet or by cross-flow holes in the angles that supported the channels of wire cloth. Wire cloth more closely meeting the specified permeability could have practically eliminated circumferential variations in wall temperature, except for those caused by any hot streaks in the combustion gas. The slight drop in cooling-air temperature (figs. 9(a) and (c)) along the length of the cooling-air passage is due to heat losses through the uninsulated shroud.

The longitudinal profiles of static pressures on both sides of the porous wall are shown at the top of figures 9(b) and (d). For the relatively high flow ratios shown (W_a/W_g of 0.0716 to 0.0951), the continuous bleeding of air through the porous wall caused a deceleration of the cooling-air flow and a corresponding rise in static pressure of the cooling air in the flow direction. With the low flow ratios of practical interest, the static pressure of the cooling air was almost independent of passage length.

The variation of pressure drop across the porous wall with distance along the wall is represented by the vertical distance between the static pressures of the cooling air and of the combustion gas. The resulting longitudinal profiles of coolant-flow ratio $(\rho V)_a/(\rho U)_g$ are shown in figures 9(b) and (d). The coolant-flow ratios for channel 9 were considerably higher than for channel 1. The differences in coolant-flow ratios are caused by the differences in permeability and the absolute pressure level in each channel. It is recalled that the air-flow calibrations of figure 7 indicate $(\rho V)_a$ is a function of the difference of the squares of the absolute static pressure on both sides of the porous wall instead of the pressure drop alone. The curves of the fraction of total cooling-air flow in each channel are almost linear and nearly identical for channels 1 and 9 (figs. 9(b) and (d)). It can be inferred, therefore, that the longitudinal addition of cooling air was almost linear through all the channels of wire cloth.

Before discussing the cooling correlation, it is of interest to determine whether there was any progressive change in the air-flow calibration of the wire cloth during the cooling investigation. A dull greasy smudge formed on the combustion-gas side of the wire cloth in spite of the cooling-air film flowing away from the wire cloth during all periods of engine operation. The smudge is visible in figure 10 to the left of the white lines. The areas to the right of the white lines have

been wiped clean with cleansing tissue to show the condition of the wire cloth after 4 hours 10 minutes of afterburning. The smudge caused no discernible effect on air-flow calibration.

Figure 11 shows the circumferential average static-pressure drop across the porous wall against orifice cooling-air flow for several levels of combustion-chamber pressure at stations 24 and 57.5. The agreement between data taken before and during the cooling investigation was excellent at all stations. On the basis of figure 11 and the close agreement between temperature-difference ratios for nonafterburning check points, it is concluded that there was no significant change in the air-flow calibration of the wire cloth during the cooling investigation.

Cooling Correlation

The experimental cooling data with afterburning are correlated over a range of Reynolds numbers in figures 12(a) to (f). Cooling data obtained from channels 1 (hottest) and 9 (coldest) met, or overlapped, to define a single curve when the Reynolds number was held approximately constant. The mean curves drawn through groups of data points having approximately the same Reynolds number are summarized in figure 12(g). Within the ranges investigated, neither Reynolds number nor radiation had any marked effect on the correlation of afterburning cooling data for coolant-flow ratios less than about 0.007. Above a coolant-flow ratio of 0.007, the temperature-difference ratio, and hence the porouswall temperature for fixed cooling-air and gas temperatures, decreased as Reynolds number increased from about 75,000 to 800,000. The curves for Reynolds numbers of 1,000,000 and 1,500,000 lie, respectively, above and below the curve for 800,000. It is probable that in this Reynolds number range, corresponding to stations 49.6 and 57.5, increases in radiant heat transfer tend to counterbalance increases in the Reynolds number (see ref. 1), although the radiant heat transfer was calculated to be less than one-tenth of the convective heat transfer.

A direct comparison between the curves of the experimental cooling correlation and those predicted by the approximate theory of references 4 and 5 is not entirely realistic because of the different assumptions used with these data and those used for developing the approximate theory. However, a partial comparison is made in appendix B.

Although nonafterburning conditions were not of primary importance to the present investigation, the nonafterburning conditions are of somewhat general interest in connection with the heat-transfer process of transpiration cooling. The combustion-gas temperature was almost constant along the length of the combustion chamber during nonafter-burning, and radiation from the gas was negligible because of the low

gas temperature and pressures. The nonafterburning cooling data are presented in tables I to IV. Nonafterburning cooling data are shown in figure 13 by plotting $(T_w - T_a)/(T_g - T_a)$ against Reynolds number for constant values of $(\rho V)_g/(\rho U)_g$. Cooling correlation curves for Reynolds numbers of 10^5 and 10^6 (fig. 14) were obtained from a cross plot of figure 13. The curves of figure 14 are similar in shape and magnitude to the afterburning data for comparable Reynolds numbers, as can be seen in figure 15. Although somewhat better cooling is indicated by the nonafterburning than by the afterburning data at coolant-flow ratios less than about 0.007, the agreement between afterburning and nonafterburning data is considered satisfactory. The agreement probably would have been closer if measured values had been available of the local combustion-gas temperatures and of $(\rho U)_g$ near the wall, instead of assuming $(\rho U)_g = W_g/A_g$. The profiles of $(\rho U)_g$ are known to differ between nonafterburning and afterburning conditions.

Transpiration-Cooling Performance

Figure 16 is a plot of the calculated maximum wall temperature against total flow ratio W_a/W_g for the assumed flight conditions A to D when operating with an exhaust-gas temperature of 3700° R. It should be emphasized that the air flow through the porous wall is a function of the difference of the squares of the absolute pressures on either side of the wall (see fig. 7). Hence the magnitude and the longitudinal position of the maximum wall temperature are functions of the profiles of the absolute static pressures and of the combustion-gas temperature. The profiles of absolute static pressure are dependent on the flight condition and the pumping characteristics of the engine used, in addition to pressure losses in the afterburner. For the flight conditions investigated, the maximum wall temperature occurred at the leading edge of the porous wall, except when the cooling-air static pressure was reduced to 10.85 pounds per square inch absolute. At this pressure, the maximum wall temperature moved to about station 49.6.

Separate curves of maximum wall temperature against total flow ratio were obtained for each flight condition (fig. 16). The curves closely overlap so that the cooling-air requirements were nearly independent of flight conditions; however, the curves would be separated more if the gas temperature had been widely varied. The operable range of total flow ratio varied with flight condition because of the related minimum and maximum pressure drops across the porous wall. The upper symbol on each curve corresponds to the assumed minimum pressure drop across the porous wall of 1 pound per square inch at the leading edge. The lower symbol corresponds to the assumed maximum pressure drop of 6 pounds per square inch at the trailing edge. The resulting minimum and maximum cooling-air pressures are given in figure 16. With a uniform distribution of cooling-air pressure,

888

the range in static pressure for control of cooling-air flow at a given flight condition is then 5 pounds per square inch minus the drop in combustion-chamber static pressure along the porous wall. Consequently, large drops in combustion-chamber pressure along the porous wall tend to decrease the range of cooling-air static pressure for control of cooling-air flow. The control range for cooling-air static pressure varied from 3.70 to 0.66 pounds per square inch, respectively, for flight conditions B and D. Cooling-air pressure must be accurately controlled within this range. For example, at flight condition D, a decrease in cooling-air static pressure of 0.66 pound per square inch (only 1.85 percent of the absolute cooling-air pressure) causes a 256° R increase in maximum wall temperature.

Greater range could be obtained in cooling-air static pressure by using several layers of wire cloth. This type of construction would permit higher pressure drops across the porous wall and would make possible the control of low flows corresponding to high maximum wall temperatures without danger of reverse flow through the wall. The peak temperature limit for the porous wall was about 1410°R because of oxidation of the brazing alloy on the wire cloth in this afterburner. Therefore, a temperature of 1210° R is assumed to be safe for the maximum wall temperatures computed from the cooling correlation. This temperature provides a 200° safety factor for local peak temperatures caused by hot streaks in the combustion gas and from small random areas of the cloth that have less than the mean permeability. A total flow ratio $W_{\rm a}/W_{\rm g}$ of about 0.032 can maintain a maximum wall temperature of 1210° R with an exhaust-gas temperature of 3700° R at conditions A to C. Calculations indicated that a maximum wall temperature of 1210° R could also be maintained at condition D by increasing the assumed maximum allowable pressure drop across the wire cloth by about 20 percent (point indicated by the end of the dotted extension). A visual extrapolation of the curves of figure 16 (disregarding pressure limits) to a wire-cloth temperature of 1760° R, which is a representative temperature for a wall of stainless steel, results in a total flow ratio of about 0.018. This value compares favorably with the total flow ratio of 0.016 computed in reference 2 for the same maximum wall temperature with a porous wall of sintered stainless steel and an exhaust-gas temperature of about 3800° R. The somewhat more effective cooling indicated for a porous wall of sintered stainless steel in reference 2 may be caused by a more uniform film of cooling air on the sintered wall than that produced by the fewer number of larger pores in the surface of the wire cloth.

A total flow ratio of 0.032 for flight conditions A to D when using a uniform permeability distribution is about 15 percent higher than the minimum total flow ratio for a constant wall temperature of 1210° R which would generally require a different permeability distribution for each flight condition. Therefore, the practicability of

using wire cloth having a nonuniform longitudinal distribution of permeability, compromising the variable permeability distributions required to maintain a constant wall temperature for each of the flight conditions investigated, is questionable.

Some reductions should be expected in the total flow ratios of transpiration-cooled afterburners if, through quality control, the tolerance on the uniformity of permeability can be decreased from that of the brazed and rolled wire cloth used. The use of porous materials having sufficient strength and resistance to oxidation at higher operating temperatures will also permit a reduction in cooling-air flow. For example, the minimum total flow ratio would decrease about 49 percent if the maximum wall temperature could be increased from 1210° to 1760° R, which may be possible for cloth woven from stainless steel or Incomel wires. It is expected that problems due to oxidation of a braze alloy can be solved by the use of high-temperature brazing alloys under development, or by the substitution of sintering for brazing.

Comparison of Transpiration and Forced-Convection Cooling

The cooling-air requirements for transpiration and forced-convection cooling of this afterburner are compared in figure 17 for exhaust-gas temperatures of 3200° and 3700° R at flight condition B. A typical maximum wall temperature for a forced-convection-cooled wall of stainless steel is 1760° R. With a maximum wall temperature of 1210° R, or limited by minimum practical pressure drop, for a transpiration-cooled wall of brazed and rolled wire cloth, the total flow ratios with transpiration cooling are about 16 percent of the convective requirements for exhaust-gas temperatures of 3200° and 3700° R. The corresponding inlet cooling-air temperatures are shown at the top of the figure to be about 635° and 444° R, respectively, for transpiration and forced-convection cooling. The higher temperature with transpiration cooling results from compressor bleed and from heat absorbed in convectively cooling the impermeable wall upstream of the porous wall.

Pressure Environment of Wire Cloth

The wire cloth successfully withstood the pressure surges of six afterburner starts and the usual pulsations in pressure during normal steady-state afterburning. Ignition of the afterburner usually caused surges in combustion-chamber static pressure to peak values of 2 to 5 inches of mercury. The surges damped out in less than 1 second to the steady-state values. The surge in combustion-chamber static pressure caused similar surges in cooling-air static pressure that varied anywhere from 0.2 to 1.0 or 1.5 inches of mercury. These surges dissipated to steady-state values in several seconds. During steady-state operation

both the cooling-air and combustion-chamber pressure traces showed background pressure pulsations of 100 cps with a total amplitude of about 0.10 to 0.15 inch of mercury superimposed with peaks up to about 1 or 2 inches of mercury total amplitude at roughly 3 cps. The duration of these peaks was about 0.01 second. In one or two instances beats were observed in the trace of combustion-chamber static pressure at a beat frequency of 7 cps with a total amplitude of about 1 to 2 inches of mercury.

CONCLUDING REMARKS

Cooling data were obtained for a transpiration-cooled afterburner having a porous combustion-chamber wall of brazed and rolled wire cloth. The data cover a range of exhaust-gas temperature from 1200° to 3340° R, total flow ratio of cooling air to combustion gas of 0.025 to 0.106, and pressure altitudes of 15,000 to 45,000 feet. The data are successfully correlated over a range of Reynolds numbers from 75,000 to 1,500,000 based on the distance downstream of the leading edge of the porous wall.

Maximum wall temperatures, based on the cooling correlation, were determined for a porous wall of uniform permeability at sea-level take-off and for flight Mach numbers of 0.8, 1.5, and 2.0 at an altitude of 35,000 feet. The cooling-air requirements were nearly independent of the flight conditions. A total flow ratio of cooling air to combustion gas of about 0.032 can maintain a maximum wall temperature of 1210° R with an exhaust-gas temperature of 3700° R. Savings in cooling air would, of course, be possible with porous material having a higher allowable maximum wall temperature.

The total flow ratios with a uniform permeability distribution and air flows sufficient to limit the maximum wall temperature to 1210° R are about 15 percent higher than the minimum total flow ratios corresponding to a variable-permeability wall with a constant wall temperature of 1210° R.

The total flow ratios of cooling air to combustion gas for a maximum wall temperature of 1210° R with the wire-cloth afterburner are about 16 percent of the total flow ratios required to convectively cool a stainless-steel afterburner wall to a maximum temperature of 1760° R with exhaust-gas temperatures of 5200° and 3700° R.

The analysis of cooling-air requirements for the previously mentioned flight conditions indicated that cooling-air static pressure must be closely controlled, especially at a flight Mach number of 2.0.

SYMBOLS

The following symbols are used in this report:

$A_{\mathbf{g}}$	combustion-chamber flow area, sq in.	بر
C _v	<pre>jet velocity coefficient, measured jet thrust divided by isentropic jet thrust for measured mass flow</pre>	3295
c p	specific heat at constant pressure	
D	inside diameter of combustion chamber, in.	
Fj,m	measured jet thrust, 1b	
g	acceleration due to gravity, ft/sec2	
Hg,c	convective heat-transfer coefficient that would apply to a solid surface under identical outside flow conditions, Btu/(sec)(sq in.)(OR)	:.
Hg,r	coefficient of nonluminous heat transfer, Btu/(sec)(sq in.)(OR)	
K	permeability coefficient, sq in. (defined in eq. (6) of ref. 3)	· -
L	distance from flame holder to exhaust-nozzle exit, 66 in.	-
Nu	Nusselt number	• ::
P .	total pressure, lb/sq in. abs	
Pr	Prandtl number	
p .	static pressure, lb/sq in. abs	-
$\Delta(p^2)$	difference between squares of absolute static pressures on both sides of porous wall, $p_a^2 - p_g^2$, $lb^2/in.^4$. :
$\log_{10}\left[\frac{\Delta(p^2)}{\tau}\left(\frac{\mu_0}{\mu}\right)^2\frac{T_0}{T}\right]$	pressure-drop parameter, $1b^2/in^{.5}$	

$(\rho V)_{a} \mu_{o} / \mu$	reduced weight flow per unit area, lb/(sec)(sq in.)
$(v_{\rm q})_{\rm g}$	coolant-flow ratio
τ	thickness of wire cloth, in.
Subscripts:	
a	cooling air
f	refers to property evaluated at film temperature $T_{\hat{\Gamma}}$
g	combustion gas
W	wall
x	at distance x
0	free-stream conditions

Numbers greater than 2 represent stations along combustion chamber in inches downstream of quick-disconnect coupling.

APPENDIX B

COMPARISON OF EXPERIMENTAL COOLING CORRELATION WITH THEORY

A brief comparison is made between the experimental cooling correlation and the approximate theory of Rannie and Friedman (refs. 4 and 5) for turbulent boundary-layer flow. The comparison is made between the temperature-difference ratio for individual data points and the theoretical temperature-difference ratio corresponding to the same experimental conditions.

The theoretical equation is given by Friedman (ref. 5) as

$$\frac{T_W - T_a}{T_g - T_a} = \frac{r}{e^{r\phi} + r - 1}$$
 (B1)

where r is the ratio of the velocity parallel to the surface at the border between the laminar sublayer and the turbulent part of the boundary layer to the stream velocity outside the boundary layer. Eckert (ref. 14) gives

$$r = \frac{2.11}{(Re)_{g}^{0.1}}$$
 (B2)

$$\Phi = \frac{(\rho V)_a c_{p,a}}{H_{g,c}}$$
 (B3)

For turbulent boundary-layer flow over a flat plate, Colburn gives

$$Nu = 0.0296(Re)^{0.8}(Pr)^{1/3}$$
 (B4)

where Re is based on the distance from the leading edge. Rearranging equation (B4) gives

$$\frac{\text{Nu}}{\text{RePr}} = \frac{\text{Hg,c}}{(\text{pU})_{\text{g}}^{\text{c}}_{\text{p,g}}} = \frac{0.0296}{(\text{Re})^{0.2}(\text{Pr})^{2/3}}$$
(B5)

from which the local value of convective heat-transfer coefficient at any station x is

$$H_{g,c,x} = \frac{0.0296(\rho U c_p)_{g,x}}{(Re)_{g,x}^{0.2}(Pr)_{g,x}^{2/3}}$$
(B6)

The effect of temperature level on the Prandtl number is so small that a mean value was used for all cases.

The effects of nonluminous radiation were accounted for by substituting the sum of the equations (B6) and (B7) for $H_{g,c}$ in equation (B3). From the data of reference 15,

$$H_{g,r,x} = \frac{0.173 \epsilon_{s}}{(144)(3600)(T_{g,x}-T_{w,x})} \left[\epsilon_{g,x} \left(\frac{T_{g,x}}{100} \right)^{4} - \alpha_{g,x} \left(\frac{T_{w,x}}{100} \right)^{4} \right]$$
(B7)

where $H_{g,r,x}$ is the heat-transfer coefficient for nonluminous radiation at station x. A value of 0.52 was used for the pseudoemissivity $\epsilon_{\rm s}$. The local values of combustion-gas emissivity $\epsilon_{\rm g,x}$ and absorptivity $\alpha_{\rm g,x}$ were based on the total fuel-air ratio and local one-dimensional values of temperature and static pressure. No distinction was made between total and static combustion-gas temperature, because the Mach numbers in the combustion chamber were low.

The density and viscosity in the Reynolds number in equation (B6) are usually based on the gas temperature just outside the boundary layer. However, in order to obtain a better correlation of heat-transfer data over a large range of $T_{\rm w}/T_{\rm g}$, the combination of equations (B3) and (B6) (ignoring radiation) was modified in reference 16 to

$$\varphi = \frac{(\text{Re})^{0.2}(\text{Pr})^{2/3}}{0.0296} \frac{(\rho V)_a}{(\rho U)_g} \frac{T_w}{T_g}$$
 (B8)

The temperature ratio T_w/T_g has the effect of evaluating the density and viscosity in the Reynolds number at the wall temperature.

In view of equation (B8), the following equation was derived for ϕ_x :

$$\phi_{x} = \frac{T_{w,x}}{T_{g,x}} \frac{1}{0.0296(\rho U c_{p})_{g,x}} + \frac{0.173 \epsilon_{g}^{+}}{(Re)_{g,x}^{0.2}(Pr)_{g,x}^{2/3}} \left[\epsilon_{g,x} \left(\frac{T_{g,x}}{100}\right)^{4} - \alpha_{g,x} \left(\frac{T_{w,x}}{100}\right)^{4}\right]$$
(B9)

3235

Equation (B9) was used in equation (B1) and found to overcorrect the theoretical temperature-difference ratio, so that the intermediate temperature ratio $T_{\rm w,x}/T_{\rm f,x}$ was used in the comparison figures 18 and 19. With afterburning, the inclusion of $T_{\rm w,x}/T_{\rm f,x}$ in equation (B9) results in theoretical wall temperatures generally higher (fig. 18(a)) than those measured. When a value of 1 is assumed for $T_{\rm w,x}/T_{\rm f,x}$, the theoretical wall temperatures are lower than those measured and the scatter is less (fig. 18(b)).

For the nonafterburning data, the inclusion of $T_{\rm W,X}/T_{\rm f,X}$ in equation (B9) results in theoretical wall temperatures that are equal to or slightly lower than those measured (fig. 19(a)). The assumption of $T_{\rm W,X}/T_{\rm f,X}$ of 1 results in a slight lowering of the theoretical wall temperatures over the entire range of temperature-difference ratio (fig. 19(b)).

The determination of an empirical coefficient or exponent for $T_{w,x}/T_{f,x}$ to produce a better agreement does not appear warranted because of differences in the assumptions made in the theory and conditions in the afterburner. Therefore, no conclusion is made as to the validity of including the temperature ratios $T_{w,x}/T_{f,x}$ or $T_{w,x}/T_{g,x}$ in the equation for Φ .

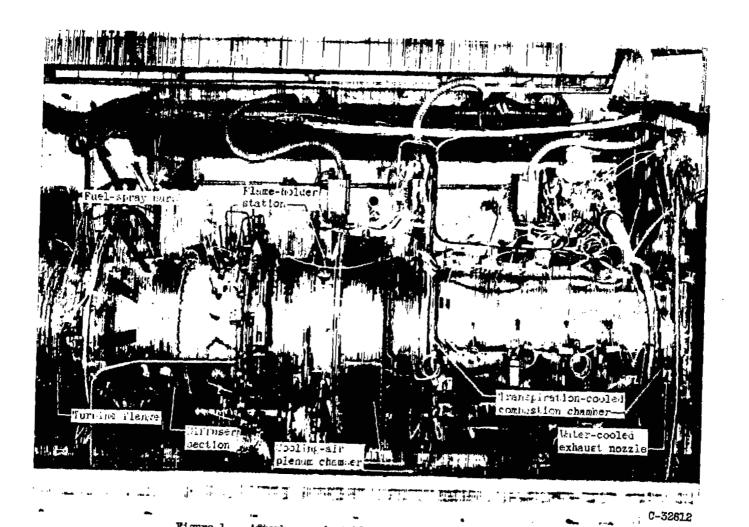

Figure 1. - Afterburner installation in altitude test chamber.

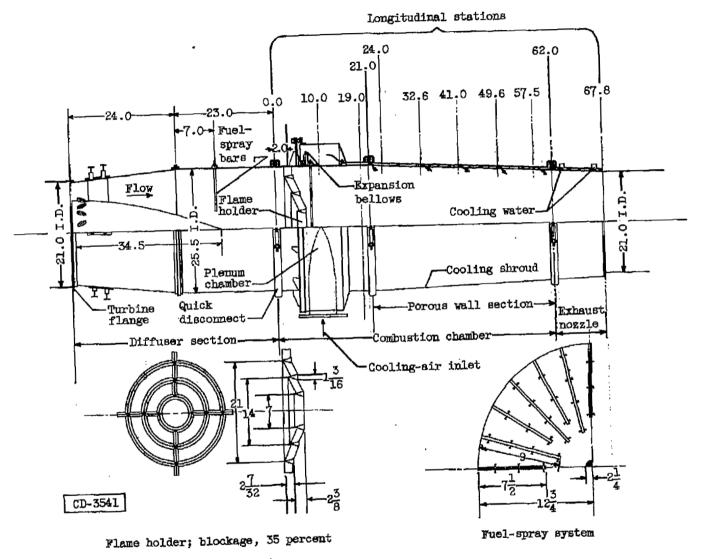

Figure 2. - Sectional view of afterburner. (All dimensions in inches.)

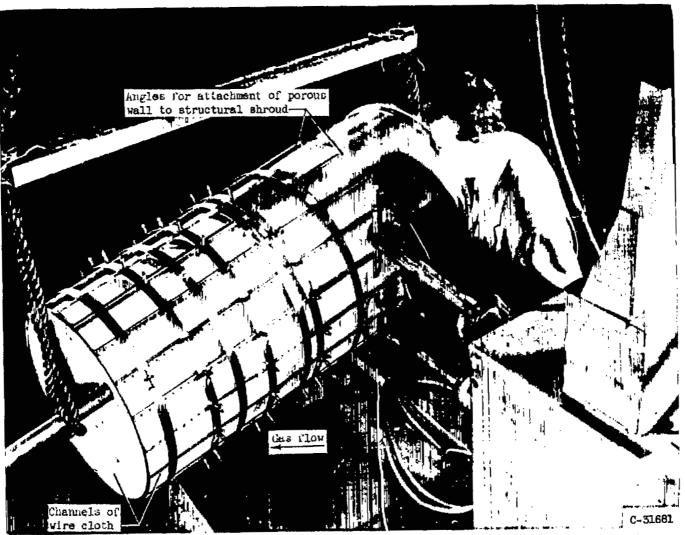

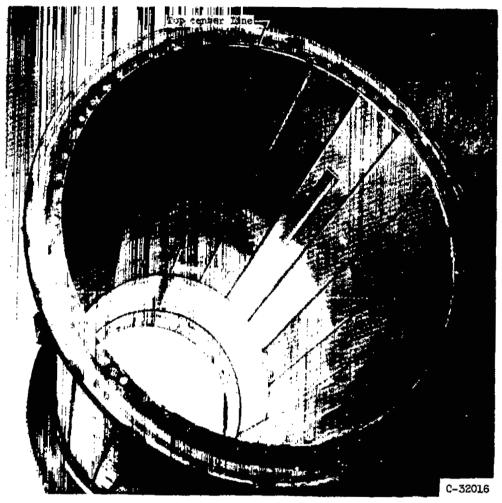

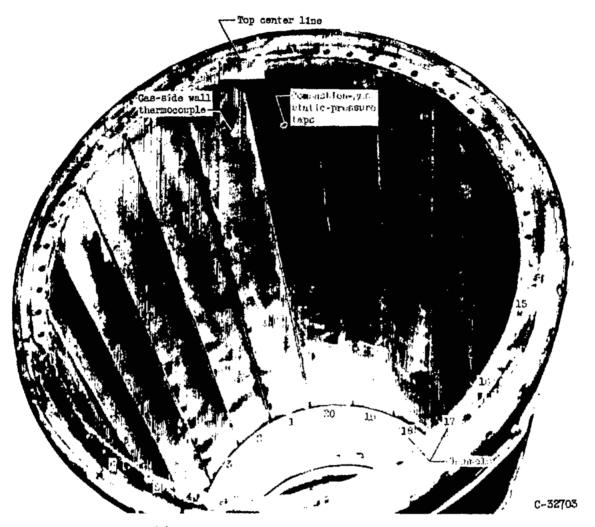

Figure 3. - Wire-cloth porous combustion-chamber wall before assembly of structural cooling shroud.

(a) Before cooling investigation.

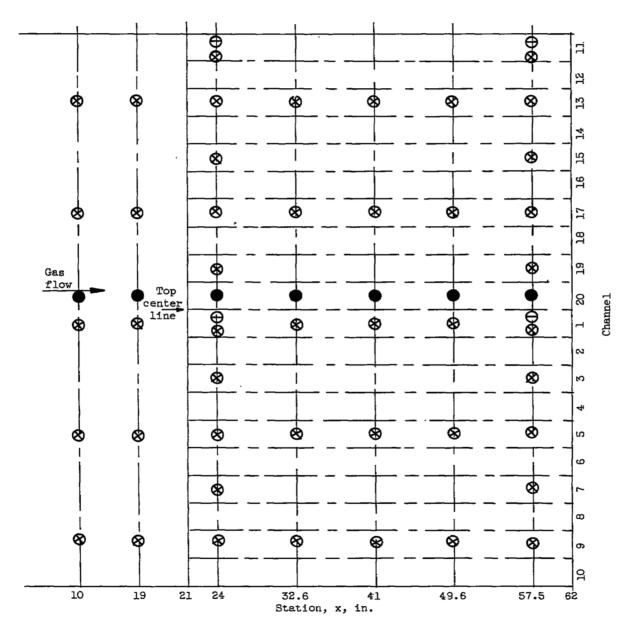

Figure 4. - Interior view of experimental transpiration-cooled afterburner with porous combustion-chamber wall fabricated from brazed and rolled wire cloth. Exhaust nozzle removed.

(b) After 4 hours 10 minutes of afterburning.

Figure 4. - Concluded. Interior view of experimental transpiration-cooled afterburner with porous combustion-chamber wall fabricated from brazed and rolled wire cloth. Exhaust nozzle removed.

- Combustion-gas static pressure
- Wire-cloth or solid metal wall air-side temperature
- O Wire-cloth gas-side temperature

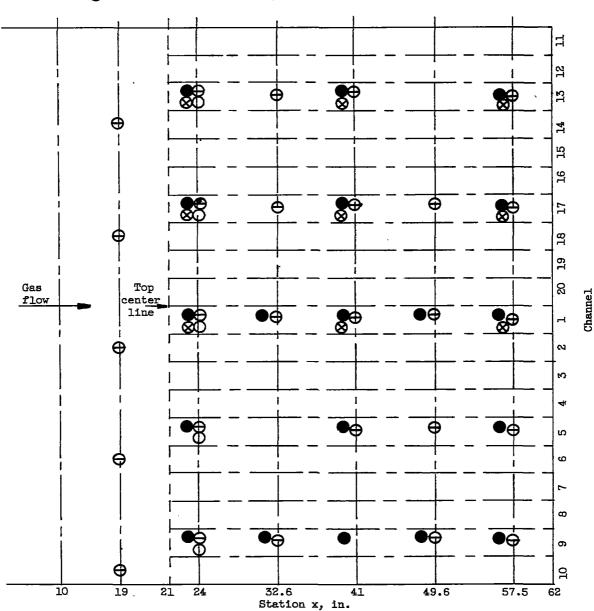

(a) Wire-cloth and combustion-gas instrumentation.

Figure 5. - Schematic development showing locations of temperature and pressure instrumentation on wire-cloth porous-wall afterburner.

- Cooling-air static pressure
- O Cooling-air total pressure
- ⊖ Cooling-air temperature
- Shroud outside-skin temperature

(b) Shroud and cooling-air instrumentation.

Figure 5. - Concluded. Schematic development showing locations of temperature and pressure instrumentation on wire-cloth porous-wall afterburner.

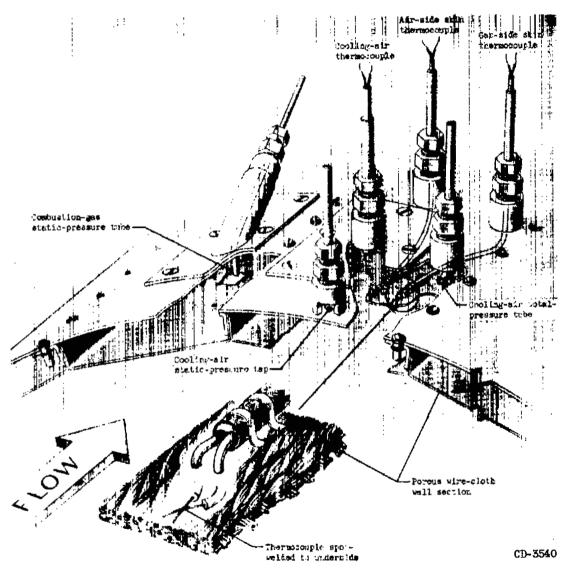

Figure 6. - Typical group of instruments on porous-wall section of wire-cloth afterburner.

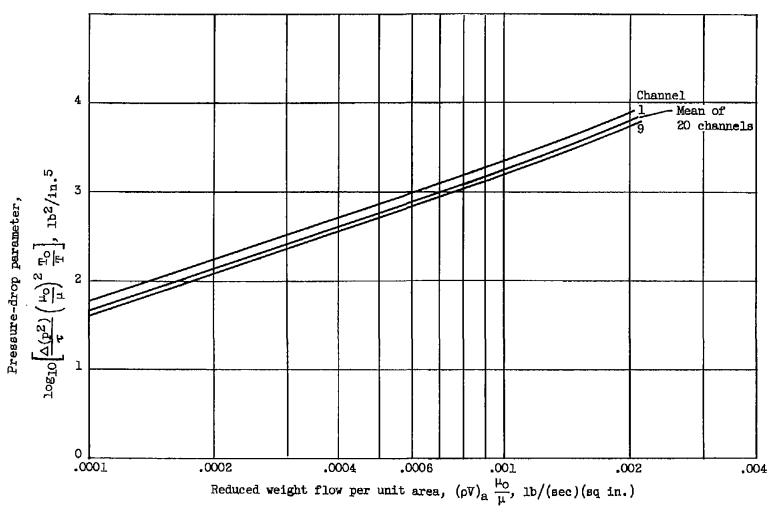

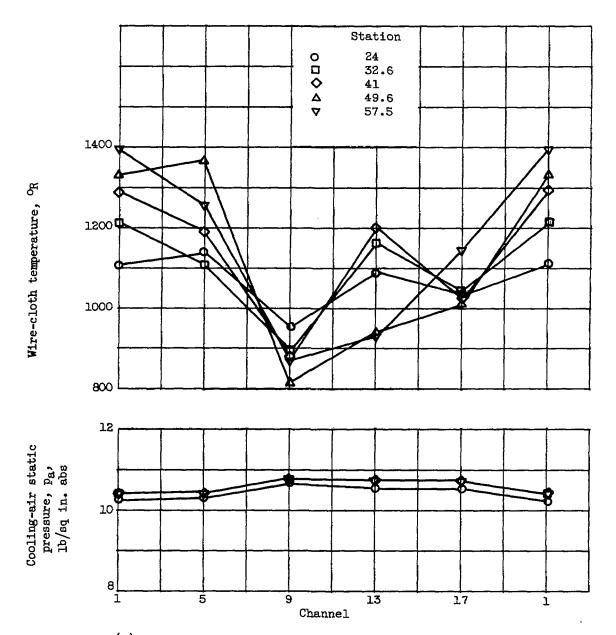

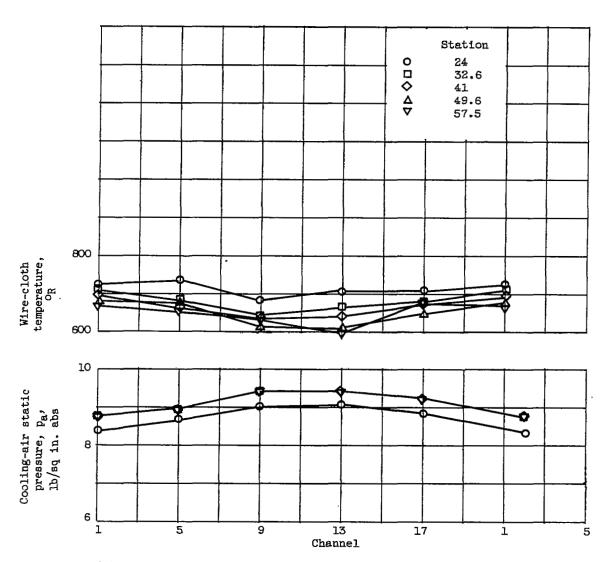

Figure 7. - Air-flow - pressure-drop calibration of wire cloth used in porous-wall section of afterburner.

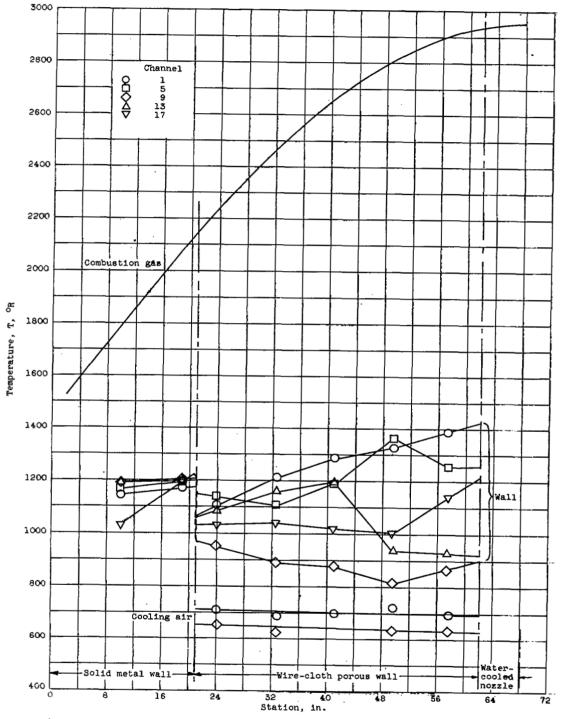

(a) Afterburning. Exhaust-gas temperature, 2954° R; total flow ratio, 0.0716.

Figure 8. - Typical circumferential profiles of wire-cloth temperature and cooling-air static pressure. Altitude, 35,000 feet; flight Mach number, 1.0.

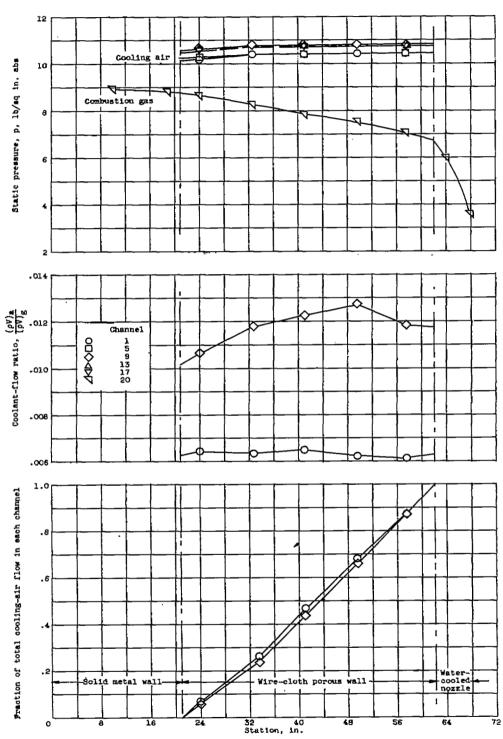

(b) Nonafterburning. Exhaust-gas temperature, 1249° R; total flow ratio, 0.0951.

Figure 8. - Concluded. Typical circumferential profiles of wire-cloth temperature and cooling-air static pressure. Altitude, 35,000 feet; flight Mach number, 1.0.

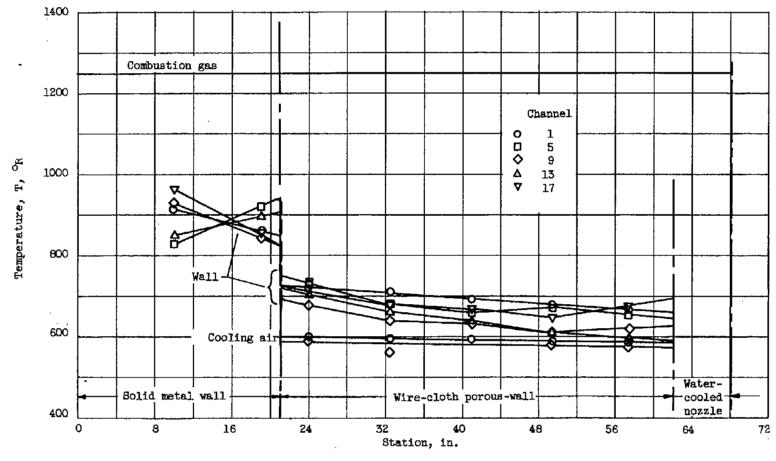

(a) Afterburning temperature profiles. Exhaust-gas temperature, 2954° R; total flow ratio, 0.0716.

Figure 9. - Typical longitudinal profiles for wire-cloth afterburner. Altitude, 35,000 feet; flight Mach number, 1.0.

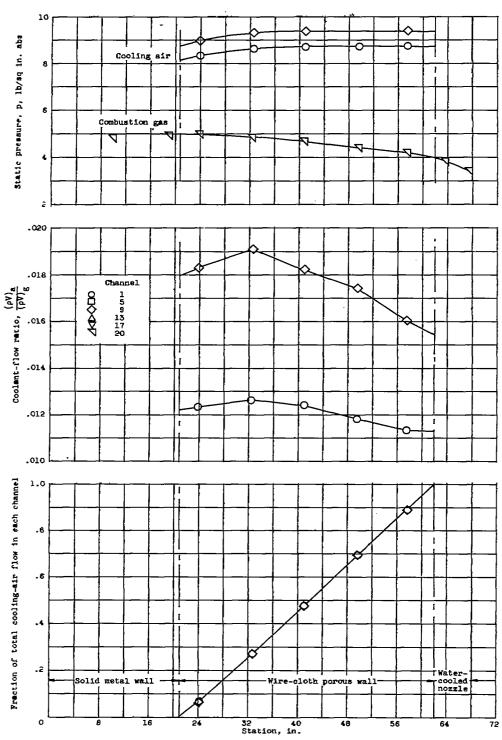

(b) Afterburning static-pressure and coolant-flow profiles. Exhaust-gas temperature, $2954^{\rm O}$ R; total flow ratio, C.0716.

Figure 9. - Continued. Typical longitudinal profiles for wire-cloth afterburner. Altitude, 35,000 feet; flight Mach number, 1.0.

(c) Nonafterburning temperature profiles. Exhaust-gas temperature, 1249° R; total flow ratio, 0.0951.

Figure 9. - Continued. Typical longitudinal profiles for wire-cloth afterburner. Altitude, 35,000 feet; flight Mach number, 1.0.

(d) Nonafterburning static-pressure and coolant-flow profiles. Exhaust-gas temperature, 1249° R; total flow ratio, 0.0951.

Figure 9. - Concluded. Typical longitudinal profiles for wire-cloth afterburner. Altitude, 35,000 feet; flight Mach number, 1.0.

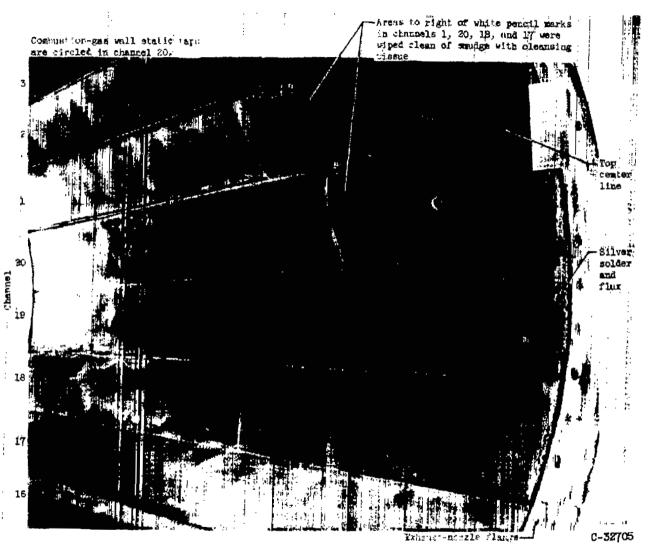

Figure 10. - Appearance of greasy smudge on wire cloth after 4 hours 10 minutes of afterburning.

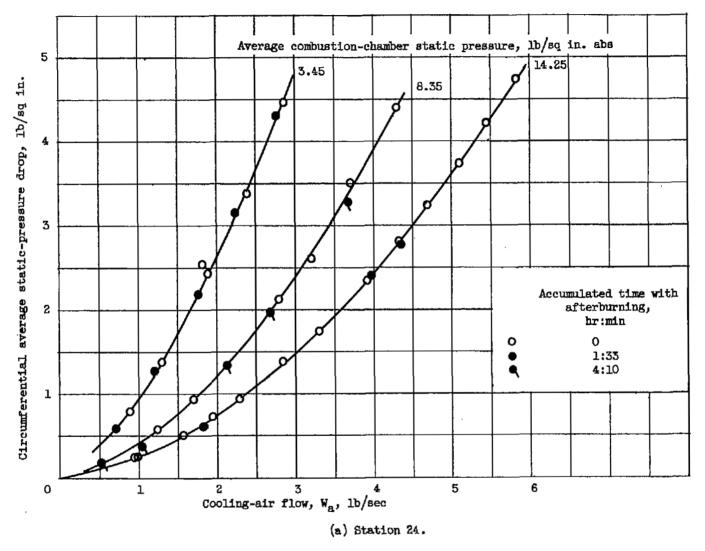

Figure 11. - Variation of circumferential average pressure drop across wire cloth with total measured cooling-air flow.

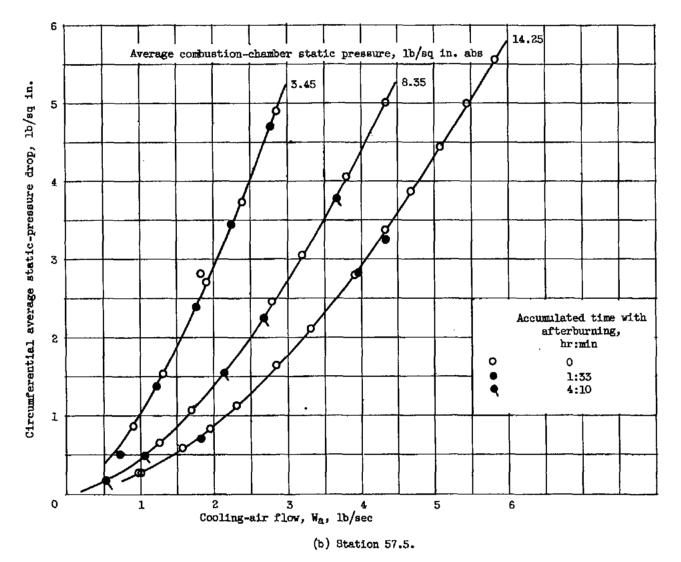

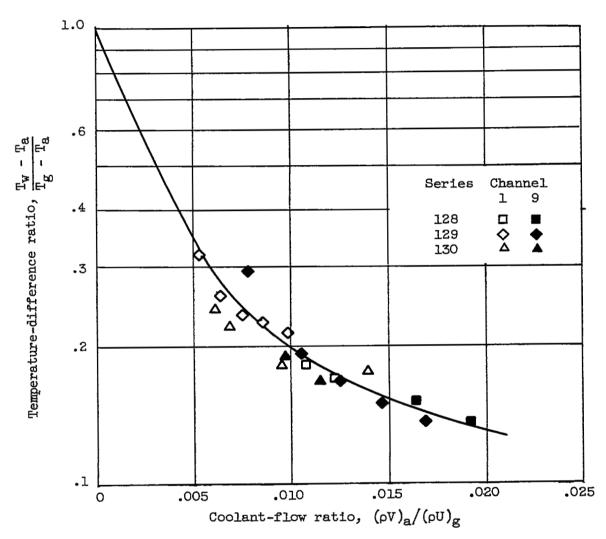

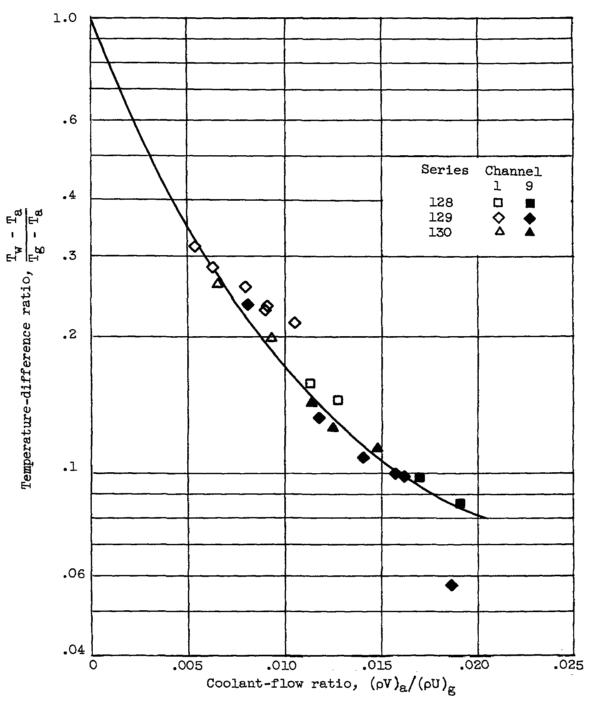

Figure 11. - Concluded. Variation of circumferential average pressure drop across wire cloth with total measured cooling-air flow.

(a) Reynolds number, approximately 75,000.

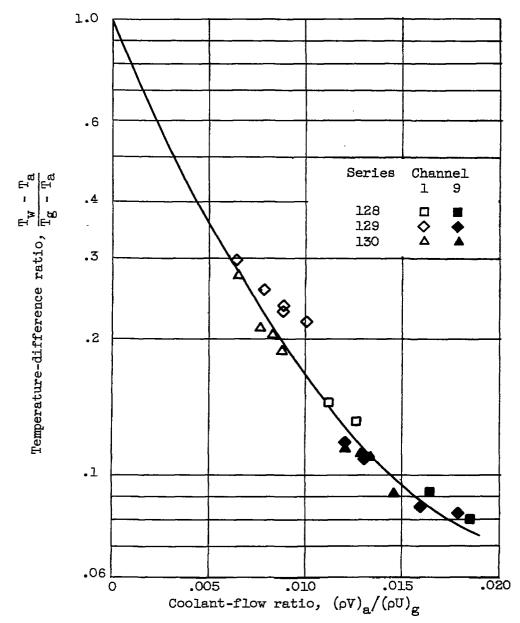

Figure 12. - Correlation of afterburning cooling data for wire-cloth afterburner.

(b) Reynolds number, approximately 300,000.

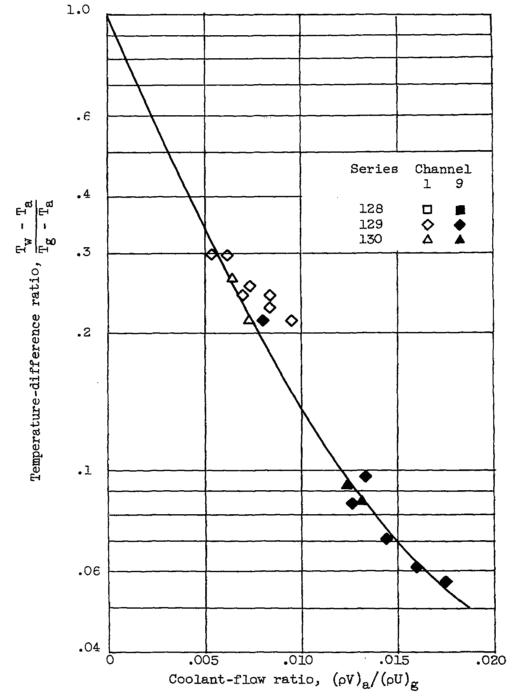

Figure 12. - Continued. Correlation of afterburning cooling data for wire-cloth afterburner.

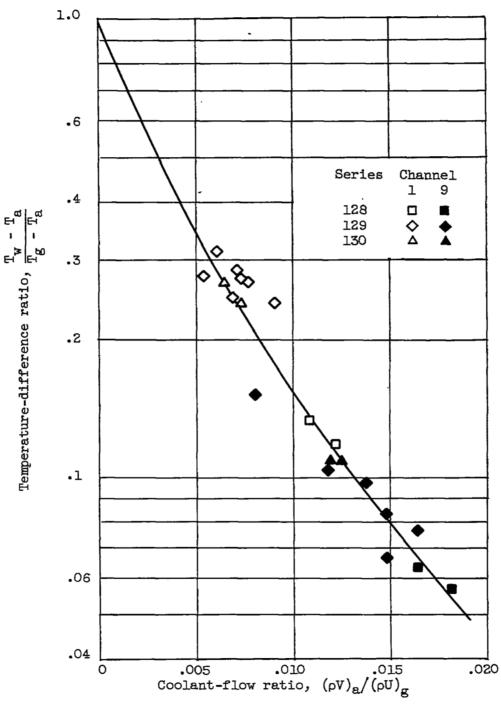

(c) Reynolds number, approximately 500,000.

Figure 12. - Continued. Correlation of afterburning cooling data for wire-cloth afterburner.

(d) Reynolds number, approximately 800,000.

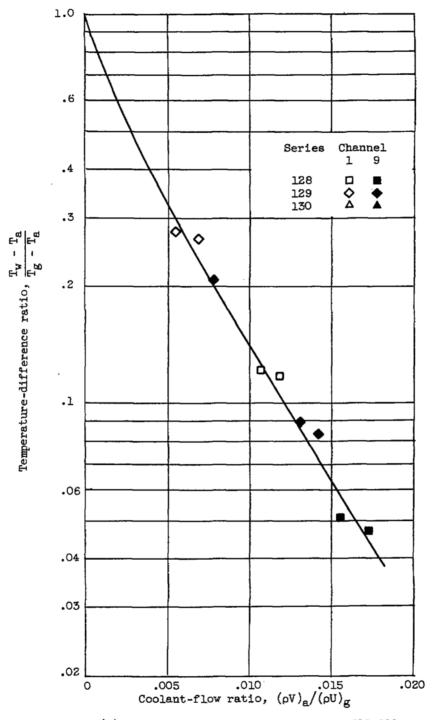

Figure 12. - Continued, Correlation of afterburning cooling data for wire-cloth afterburner.

(e) Reynolds number, approximately 1,000,000.

Figure 12. - Continued. Correlation of afterburning cooling data for wire-cloth afterburner.

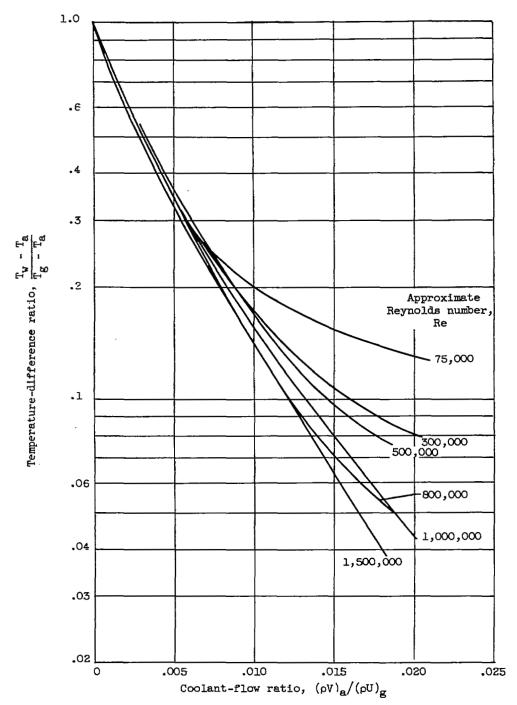

(f) Reynolds number, approximately 1,500,000.

Figure 12. - Continued. Correlation of afterburning cooling data for wire-cloth afterburner.
